

What Financial Statements Can and Cannot Reveal About Monetary Transmission to Corporate Balance Sheets: A Five-Country Emerging-Market Test

Abstract

Firms holding floating-rate debt bear the brunt of monetary tightening—a finding built almost entirely on supervisory credit registries. Most emerging markets have none; they have published financial statements. Can these substitute? We develop a measurement framework in which exposure is estimated rather than observed, and test its predictions on harmonised panels of listed non-financial firms in five emerging markets—Türkiye, Vietnam, Poland, Israel and South Korea—over 2010–2025 (2021–2025 for the latter three), spanning tightening doses from Türkiye’s 36.0 percentage points to Vietnam’s 1.5. The price of debt proves recoverable: a simple implied borrowing cost tracks each country’s policy path, and its change correlates with tightening dose at $r = 0.995$ across the sample, with pass-through of roughly one-third in Türkiye and coverage halving. Exposure does not. Split-half reliabilities of +0.045 and +0.054 in the two countries with decade-long history are indistinguishable from zero, implying an attenuation factor of essentially zero, Türkiye’s inflation-accounting restatement enters as an exposure-by-post interaction fixed effects cannot absorb, and pooling all five countries the exposure-by-dose interaction is null on interest coverage and profitability ($p = 0.84$, $p = 0.41$) while significant only on the price measure already

shown to move with dose mechanically. The contractual object these designs require is absent from the accounting record.

Keywords: monetary transmission, corporate default, measurement error, inflation accounting, emerging markets, financial statements

1. Introduction

A firm that borrows at a floating rate feels a policy tightening within weeks. A firm that borrowed long and fixed does not feel it until it refinances. This asymmetry is simple, intuitive, and has become the organising principle
5 of a productive literature on how monetary policy reaches the corporate sector. Ippolito et al. (2018) identify a *floating rate channel* in matched loan-level records, showing that firms with unhedged floating-rate bank debt cut investment and employment more sharply after tightening. Şengül and Çinko (2026), studying the June 2023 policy reversal in Türkiye, apply a
10 two-part Double Machine Learning design to a large administrative dataset and find that while the average effect is modest, sensitivity concentrates in firms with weak internal risk ratings, low liquidity and high exposure shares, with exporters and manufacturers relatively insulated.

What these studies share is not merely a question but an input: a credit
15 registry recording, loan by loan, whether the contract reprices. Such registries exist in relatively few jurisdictions and are available to researchers in fewer still. What almost every market does have is a body of audited, published financial statements. The question this paper takes seriously—and, we argue, the field has not asked carefully enough—is whether that accounting record

20 can stand in for the registry.

The stakes are practical. If statements suffice, the literature’s geographic reach expands by an order of magnitude. If they do not, then a body of work is being built on designs that cannot deliver what they promise, and it is worth establishing precisely where the failure occurs and what remains
25 possible.

1.1. Approach

We proceed in two stages. Section 2.2 develops a measurement framework in which the exposure variable is *estimated* rather than observed, and derives what that implies for the difference-in-differences estimand. The framework
30 delivers four propositions, each of which generates a sharp, falsifiable prediction about statistics we can compute. Sections 3.1–5.4 take those predictions to data.

The empirical design is comparative and, where the data permit, decade-long. Vietnam and Türkiye anchor the study: they share the structural fea-
35 tures that make the floating-rate channel plausible—bank-dominated corporate finance, thin corporate bond markets, heavy reliance on short-maturity credit, substantial listed non-financial sectors—and diverge sharply in monetary experience. Türkiye executed one of the decade’s most severe tightenings, from 9.0% to 50%, under inflation exceeding 60%; Vietnam tightened
40 modestly in late 2022 and reversed within a year. Both countries carry the history needed to test the identifying assumption directly, back to 2010–11.

A two-point contrast, however sharp, is still only two points, and a referee is right to ask whether either country’s null is idiosyncratic. We therefore extend the design to three further emerging markets—Poland, Israel

45 and South Korea—spanning tightening doses of 5.0, 4.65 and 2.5 percentage points and chosen, among a broader set of markets assembled during scoping, for the largest and most reliable firm counts.¹ Across the five countries the change in implied borrowing cost correlates with tightening dose at $r = 0.995$ (Section 5.3), and the exposure-by-dose interaction is null on distress and
50 profitability outcomes regardless of how severely a country tightened. The two-country design supplies the depth—a decade of history, a testable pre-trend, an inflation-accounting stress test; the five-country extension supplies breadth, showing the conclusion is not an artefact of which two countries were chosen.

55 This dose gradient is the paper’s instrument throughout. It imposes a

¹Four further markets were assembled on the same basis during scoping and are not carried into the reported five-country test, and we name all four rather than a convenient subset. Chile (7.25pp dose, 80 firms) sits squarely on the same dose-response line as the five reported countries; its exclusion is for parsimony alone. Brazil (5.75pp dose, 215 firms) is the one clear outlier in the full assembled set, with a change in implied borrowing cost of only 0.48 percentage points against a pass-through ratio roughly a quarter of every other country’s— 0.48/5.75 against a range of 0.16 to 0.62 elsewhere. We report this so the reader can judge for themselves: the five-country correlation below is not conditioned on having found and discarded an inconvenient point after the fact, but its absence should be read as a reduction in scope, not as evidence that Brazil disproves the pattern. Hungary (24 firms) and Mexico (19 firms) were excluded for the reason given in the text: samples thinner than the 83-firm Turkish sample already shown, in Section 5.4, to produce a false positive before the sample expanded. A sixth market, Thailand, was attempted on the same basis and yielded no usable data at all—every ticker returned an empty statement, evidently a data-vendor outage rather than a substantive gap—and is recorded here for completeness rather than omitted from the account of what was tried.

discipline a single-country study cannot: a measurement strategy that works should register a stronger response where tightening was more severe, in proportion. A method that fails to register the gradient, or that finds a firm-level exposure effect that itself fails to scale with dose, has failed a test it would never have faced with one country alone.

We are conscious that five countries is not many, and Section 5.3 returns to this directly: with so few points a very high correlation is not, on its own, strong statistical evidence, and we read it qualitatively rather than as a precisely estimated slope.

Our diagnostic standard throughout is *validation against an external benchmark*. We do not ask whether a measure is statistically well behaved; we ask whether it recovers something independently known. For the price of debt, the benchmark is the published policy path. For exposure, it is the firm’s own subsequent change in borrowing cost. For the panel, it is an independent commercial rendering of the same filings.

1.2. What we find

The constructive half of the answer concerns the *price* of corporate debt. A firm’s implied borrowing cost—interest expense divided by average debt—aggregates to a series reproducing each central bank’s policy path without being shown it. The Turkish series peaks in 2024, the year policy peaks; the Vietnamese series traces the 2011 inflation crisis, the long easing through 2015, and the 2023 tightening. This establishes that ordinary filings carry a legible signal of monetary transmission.

Two results follow. We quantify pass-through: a 41.0 percentage point Turkish policy move—from the 9.0% low point at end-2022 to the true 2024

peak of 50%, sustained March through November before a December cut to 47.5%—produces a 13.4 point move in realised borrowing costs, roughly a third, while median interest coverage halves from 3.36 to 1.66. Section 2.2 shows how to read that number structurally as an effective repricing share.

85 Second, the same diagnostic exposes a data hazard: a widely used Turkish vendor field labelled *Financial Expenses* bundles foreign-exchange revaluation with interest, running roughly two and a half times the true figure, so measures built on it peak in the lira crises of 2018 and 2021 rather than at the 2024 policy peak.

90 The cautionary half concerns *exposure*, and here theory and evidence coincide exactly. Proposition 1 shows that using an estimated exposure attenuates the estimand by the reliability ratio λ . Proposition 2 shows λ is identified by the split-half correlation of independently estimated exposures. We measure that correlation at +0.045 in Türkiye and +0.054 in Vietnam, implying
95 $\hat{\lambda} \approx 0$: the estimand is attenuated to zero regardless of the true effect, and a null is therefore uninformative about the underlying parameter. Proposition 4 derives the panel length required for feasible estimation and shows annual accounting data falls short by roughly an order of magnitude. Proposition 6 derives the in-sample fit expected under the null, $k/(T - 1) \approx 0.50$,
100 against observed medians of 0.66 in Vietnam and 0.71 in Türkiye—not an exact match, but the same order of magnitude as chance, which is the point: a two-parameter fit on five annual observations looks moderately good whether or not the relationship is real.

Layered on top is a problem specific to high-inflation settings. Proposition 7 shows that when non-monetary assets are restated by a vintage-
105

dependent factor while monetary debt is not, the distortion enters as an exposure-by-post interaction that two-way fixed effects cannot absorb. Proposition 8 shows that ratios of two flows escape it. We demonstrate the former empirically: a standard specification returns highly significant wrong-signed coefficients on a monotonically growing post-treatment path.

1.3. Why a null of this kind is informative

Null results invite the suspicion of low power, and we address it directly. Over the analysis three separate significant results appeared and each was shown to be an artefact: a Turkish effect of +0.886 ($p = 0.045$) that vanished when the sample doubled; the FX results, which were accounting restatement; and the final flow-based coefficients, which were pre-existing trend. Each was caught by a diagnostic—sample expansion, an accounting-mechanics argument, an extended event window—that a conventional specification would not have run. A design generating three false positives before generating a null is informative about the design.

1.4. Contribution

To the transmission literature we delimit where statement-based designs can substitute for registry data, and supply a validated price measure that survives. To empirical work on Türkiye we document two hazards—one in a vendor field, one in the accounting standard—threatening a broad class of post-2022 studies. To research on Vietnam we introduce a firm-level statement panel not previously used for such questions. Methodologically, we offer split-half reliability and first-stage prediction as cheap, decisive tests

that any paper using an estimated firm characteristic as a regressor should
130 report, and we give them a formal justification.

2. Related literature and analytical framework

2.1. Related literature

2.1.1. Firm heterogeneity in monetary transmission

That monetary policy affects firms unequally is long established. Gertler
135 and Gilchrist (1994) documented that small manufacturing firms bear a disproportionate share of the adjustment following tightening, and Bernanke and Gertler (1995) formalised the credit channel through which balance-sheet strength mediates the response. Kashyap and Stein (2000) established the bank lending channel using cross-sectional variation in bank liquidity.

140 The modern literature has sharpened the relevant margin. Ottonello and Winberry (2020) show that firms with low default risk respond *most* to monetary shocks, because they face flatter marginal cost curves for external finance. Cloyne et al. (2023) find that younger firms without dividend payments drive the investment response. Ozdagli (2018) shows that financial frictions shape the stock price reaction to policy, and Greenwald (2019)
145 identifies an interest coverage channel operating through debt covenants—directly relevant to our outcome set, since coverage is one of the few distress measures that survives Proposition 8.

Two strands bear closely on our design. The first concerns *contractual*
150 repricing: Ippolito et al. (2018) identify the floating rate channel using loan-level data, and Auer et al. (2019) trace international transmission through banks in small open economies. The second concerns *maturity*: Almeida

et al. (2012) exploit quasi-random variation in whether long-term debt hap-
pened to mature just before the 2007 crisis, a design that isolates rollover
155 exposure cleanly; Jungherr et al. (2024) show maturity structure materially
shapes transmission; He and Xiong (2012) provide the theoretical link be-
tween rollover and credit risk; and Demirgüç-Kunt and Maksimovic (1999)
document how institutions shape maturity choice across countries.

Our contribution is not to this literature’s substance but to its trans-
160 portability. Every study cited uses either supervisory data or a market with
rich contractual disclosure. We ask what remains when neither is available,
and Section 2.2 shows the answer is not simply “a noisier version of the same
design”.

2.1.2. Firm-level evidence on Türkiye and comparable markets

165 A body of firm-level work situates our exercise in the Turkish setting.
Bilgin et al. (2023) study Borsa Istanbul firms directly and, importantly for
us, exploit the *maturity breakdown* of bank credit in explaining corporate
performance—establishing both that maturity structure is economically con-
sequential in this market and that it is recoverable from disclosure. Sugo-
170 et al. (2025) apply machine-learning methods to credit risk in Turkish partic-
ipation and conventional banks. On the macro-financial side, Çitçi and Kaya
(2023) analyse exchange-rate uncertainty and the connectedness of inflation
in Türkiye, and Akbal and Cıvcır (2026) the asymmetric response of the
lira to capital flows and sovereign spreads. Together these establish the two
175 forces our measurement must separate—interest rates and the currency—as
first-order in this economy.

A parallel literature examines firm financing structure in comparable mar-

kets: Çam and Özer (2022) on how country governance shapes capital structure and investment financing, Karakoç (2022) on the corporate growth–trade
180 credit relationship across a panel of countries, and Huynh (2024) on banking uncertainty and trade credit. What these share with our setting is a reliance on published statements rather than supervisory records, which is precisely why the measurement limits we establish bear on them.

Our reading of this literature is that it has been appropriately cautious in
185 what it asks of accounting data—studying maturity composition, credit type and financing structure, all of which are disclosed—and that the floating-rate question is different in kind because its treatment variable is not.

2.1.3. Currency mismatch in emerging markets

Because Türkiye’s episode combines tightening with severe depreciation,
190 the FX-mismatch literature bears directly on our measurement problem. Eichengreen and Hausmann (1999) framed the “original sin” of borrowing in foreign currency. The empirical record is more nuanced than the framing suggests: Bleakley and Cowan (2008) find that firms holding dollar debt did not systematically underperform during depreciations, because they tended
195 to hold dollar revenues too, while Aguiar (2005) documents contractionary balance-sheet effects in Mexico. Kalemli-Ozcan et al. (2016) reconcile these by showing that the damaging combination is unhedged FX debt together with a banking crisis restricting credit supply.

Bruno and Shin (2015b,a) establish the risk-taking channel linking ex-
200 change rates, bank leverage and global liquidity; Du and Schreger (2022) connect sovereign risk, currency risk and corporate balance sheets; Acharya et al. (2024) show how impaired credit allocation distorts inflation dynamics.

For Türkiye, Akbal and Civeir (2026) examine the asymmetric response of the lira to capital flows and sovereign spreads.

205 This literature matters to us twice over. Substantively it explains why exporters may be insulated—a mechanism Şengül and Çinko (2026) invoke directly, noting that exporters generate foreign-currency revenues and benefit from exchange-rate pass-through. Methodologically it explains why the bundled financial-expense field of Section 4.1 is so damaging: in a currency crisis
210 revaluation losses dwarf interest, and a measure conflating them attributes currency effects to monetary policy.

2.1.4. Accounting measurement under inflation

Our identification problem is at bottom an accounting one, and there is a literature on it that monetary economics rarely cites. Gordon (2001) exam-
215 ines the value relevance of historical cost, price level and replacement cost accounting in Mexico; Barniv (1999) studies inflation-adjusted versus historical-cost earnings under hyperinflation; Davis-Friday and Gordon (2005) analyse how the valuation roles of book value, earnings and cash flows shift during a macroeconomic shock; and Konchitchki (2011) demonstrates that nominal
220 reporting has real consequences even at moderate inflation. De Franco et al. (2011) show that statement comparability is itself economically consequential.

The consistent message is that when general price levels move sharply, the mapping from economic reality to reported figures changes, and changes
225 *differently across firms*. Proposition 7 gives this literature what we believe is a novel application: an accounting transition coinciding with a treatment date and interacting with the treatment variable is not a nuisance to be

absorbed but a threat to identification.

2.1.5. *Measurement error and generated regressors*

230 Our exposure results connect to a developed econometric literature. Pagan (1984) established the consequences of using a regression-generated variable as a regressor in a second stage, which is precisely our situation. Griliches and Hausman (1986) show that panel transformations frequently *amplify* rather than attenuate measurement error—directly relevant, since first-differencing
235 in (6) removes the fixed effect but magnifies the noise-to-signal ratio. Classical attenuation biases coefficients toward zero, exactly the pattern our null exhibits, which is why we regard a first-stage validity test as obligatory rather than optional.

Proposition 5 extends this in a direction we have not seen applied to firm-
240 level exposure: separating estimation error from genuine impermanence of the underlying characteristic. The distinction is consequential because the two failure modes call for opposite responses.

2.2. *An analytical framework for estimated exposure*

This section formalises what is at stake when the exposure variable of a
245 difference-in-differences design is estimated from accounting data rather than observed contractually. The framework is deliberately spare, and each result generates a statistic we compute in Sections 4.1–5.1.

2.2.1. *Setup*

Index firms by $i = 1, \dots, N$ and years by $t = 1, \dots, T$. Let π_t denote
250 the policy rate and f_t the log exchange rate. Let $P_t = \mathbf{1}\{t \geq t^*\}$ be the post-treatment indicator, with t^* the tightening date.

Each firm has a latent *repricing exposure* θ_i , defined as the share of its debt whose contractual rate resets within the period. The object of interest is the effect of tightening on a distress outcome Y_{it} , mediated by exposure:

$$Y_{it} = \beta (\theta_i P_t) + \alpha_i + \lambda_t + \varepsilon_{it}, \quad \mathbb{E}[\varepsilon_{it} \mid \theta_i, P_t] = 0, \quad (1)$$

255 with firm effects α_i and year effects λ_t . If θ_i were observed, β would be identified by the two-way within estimator. The registry literature is, in effect, the case in which θ_i is observed.

Our situation is that θ_i is not disclosed. We observe instead a proxy

$$\hat{\theta}_i = \theta_i + u_i, \quad u_i \perp (\theta_i, \varepsilon_{it}), \quad \text{Var}(u_i) = \sigma_u^2, \quad \text{Var}(\theta_i) = \sigma_\theta^2. \quad (2)$$

Define the *reliability ratio*

$$\lambda \equiv \frac{\sigma_\theta^2}{\sigma_\theta^2 + \sigma_u^2} \in [0, 1]. \quad (3)$$

260 *2.2.2. Attenuation of the treatment estimand*

Proposition 1 (Attenuation). *Let $\hat{\beta}$ be the two-way within estimator of (1) obtained by replacing θ_i with $\hat{\theta}_i$. Then*

$$\text{plim}_{N \rightarrow \infty} \hat{\beta} = \lambda \beta. \quad (4)$$

Proof. Write the regressor as $X_{it} = \hat{\theta}_i P_t$ and let $\tilde{X}$ denote its residual after projecting out firm and year effects. Because P_t varies only over time and $\hat{\theta}_i$ only across firms, the within transformation yields $\tilde{X}_{it} = (\hat{\theta}_i - \bar{\theta})(P_t - \bar{P})$.
265 Using (2) and $u_i \perp \theta_i$,

$$\text{Cov}(\tilde{Y}, \tilde{X}) = \beta \sigma_\theta^2 \text{Var}(P), \quad \text{Var}(\tilde{X}) = (\sigma_\theta^2 + \sigma_u^2) \text{Var}(P).$$

The ratio is $\lambda\beta$. □

Proposition 1 is the classical attenuation result (Pagan, 1984) transposed to an interaction term, and it has an uncomfortable implication: a statistically insignificant $\widehat{\beta}$ is consistent with *any* value of β once λ is small. A null
270 is therefore uninterpretable without an estimate of λ .

2.2.3. Identifying the reliability ratio

The natural objection is that λ is unobservable because θ_i is. It is not, provided two independent proxies can be constructed.

275 **Proposition 2** (Split-half identification). *Let $\widehat{\theta}_i^{(1)} = \theta_i + u_i^{(1)}$ and $\widehat{\theta}_i^{(2)} = \theta_i + u_i^{(2)}$ be estimated on disjoint subsamples, with $u^{(1)} \perp u^{(2)}$ and $\text{Var}(u^{(1)}) = \text{Var}(u^{(2)}) = \sigma_u^2$. Then*

$$\text{Corr}(\widehat{\theta}^{(1)}, \widehat{\theta}^{(2)}) = \frac{\sigma_\theta^2}{\sigma_\theta^2 + \sigma_u^2} = \lambda. \quad (5)$$

Proof. $\text{Cov}(\widehat{\theta}^{(1)}, \widehat{\theta}^{(2)}) = \text{Var}(\theta) = \sigma_\theta^2$ since the errors are mutually independent and independent of θ . Each variance is $\sigma_\theta^2 + \sigma_u^2$. $\square$

280 **Corollary 3.** *If the split-half correlation is not bounded away from zero, then $\text{plim } \widehat{\beta} = 0$ irrespective of β , and the estimated treatment effect carries no information about the structural parameter.*

This is, to our knowledge, an underused device. The split-half correlation is trivial to compute whenever exposure is estimated from a time series, and
285 by Proposition 2 it is the attenuation factor rather than merely a diagnostic correlated with it. Section 4.2 reports values of +0.045 and +0.054.

2.2.4. Feasibility: how long a panel is required?

Corollary 3 raises the question of whether a longer panel would rescue the design. It can be answered analytically.

290 Suppose exposure is estimated firm by firm from the first-differenced regression

$$\Delta r_{it} = a_i + \theta_i \Delta \pi_t + \gamma_i \Delta f_t + \eta_{it}, \quad \text{Var}(\eta_{it}) = \sigma_\eta^2, \quad (6)$$

where r_{it} is the firm's realised borrowing cost. With T usable observations per firm, sample variance s_π^2 of $\Delta \pi_t$, and correlation ρ between $\Delta \pi_t$ and Δf_t , the sampling variance of the OLS estimate is

$$\text{Var}(\hat{\theta}_i) = \frac{\sigma_\eta^2}{T s_\pi^2 (1 - \rho^2)} \equiv \sigma_u^2. \quad (7)$$

295 **Proposition 4** (Feasibility condition). *Attaining reliability $\lambda \geq \lambda^*$ requires*

$$T \geq \frac{\lambda^*}{1 - \lambda^*} \cdot \frac{\sigma_\eta^2}{s_\pi^2 (1 - \rho^2) \sigma_\theta^2}. \quad (8)$$

Proof. Substitute (7) into (3) and solve the inequality $\sigma_\theta^2 / (\sigma_\theta^2 + \sigma_u^2) \geq \lambda^*$ for T . $\square$

Every quantity on the right is estimable, so (8) can be taken to data. When we do so in Section 4.2 the condition looks satisfied: sampling noise
 300 implies $\lambda \approx 0.923$ in Vietnam, comfortably above conventional reliability thresholds, and 0.664 in Türkiye, at or above the more permissive end of them—so a conventional power calculation would have judged the design feasible, or close to it, at the available panel length.

That verdict is contradicted by the split-half correlations, which are close
 305 to zero (Section 4.2 reports +0.054 and +0.045). The contradiction is informative, and resolving it requires enriching (2).

2.2.5. Permanent, transitory and sampling components

Suppose the quantity a firm-level regression recovers is not a fixed trait but a window-specific realisation,

$$\theta_i^{(w)} = \theta_i + \nu_i^{(w)}, \quad \text{Var}(\nu_i^{(w)}) = \sigma_\nu^2, \quad (9)$$

310 where θ_i is a persistent characteristic and $\nu_i^{(w)}$ a transitory component that is real within window w —the firm genuinely did reprice that way over those years—but does not carry across windows. The estimated slope is then $\widehat{\theta}_i^{(w)} = \theta_i + \nu_i^{(w)} + u_i^{(w)}$.

Proposition 5 (Three-way decomposition). *Under (9) with ν , u mutually*
 315 *independent and independent of θ ,*

$$\text{Var}(\widehat{\theta}_i^{(w)}) = \sigma_\theta^2 + \sigma_\nu^2 + \sigma_u^2, \quad \text{Corr}(\widehat{\theta}^{(1)}, \widehat{\theta}^{(2)}) = \frac{\sigma_\theta^2}{\sigma_\theta^2 + \sigma_\nu^2 + \sigma_u^2}, \quad (10)$$

so the split-half correlation identifies the permanent share alone, and

$$\sigma_\nu^2 = \text{Var}(\widehat{\theta})(1 - \text{Corr}) - \sigma_u^2. \quad (11)$$

Moreover, Proposition 1 continues to hold with λ equal to this permanent share, since only θ_i is stable enough to interact with a treatment occurring after the estimation window.

320 *Proof.* The variance decomposition is immediate from independence. The covariance across windows is $\text{Var}(\theta) = \sigma_\theta^2$ because both ν and u are window-specific. Rearranging gives σ_ν^2 . $\square$

Proposition 5 separates two failure modes that are easily conflated. *Imprecision* (σ_u^2 large) is remediable by more data. *Impermanence* (σ_ν^2 large) is

325 not: no amount of additional data makes a transitory quantity a usable pre-
determined regressor. The empirical decomposition in Section 4.2 attributes
94.6% of Vietnamese and 95.5% of Turkish dispersion in estimated slopes to
the transitory component and only a small remainder to the permanent one—
so the binding problem is impermanence, and quarterly estimation would not
330 solve it.

2.2.6. In-sample fit is not evidence

A researcher inspecting (6) would observe a respectable R^2 and might
conclude the specification has content. It does not.

Proposition 6 (Null benchmark for fit). *Under the null that neither regres-*
335 *sor enters (6), with k regressors excluding the intercept and T observations,*
the coefficient of determination satisfies

$$R^2 \sim \text{Beta}\left(\frac{k}{2}, \frac{T-k-1}{2}\right), \quad \mathbb{E}[R^2] = \frac{k}{T-1}. \quad (12)$$

Proof. Standard: under the null the explained and residual sums of squares
are independent χ^2 variates with k and $T-k-1$ degrees of freedom, so their
normalised ratio is Beta distributed with the stated parameters, whose mean
340 is $k/(T-1)$. □

With $k = 2$ and a median of $T = 5$ usable observations on the split-
half windows this benchmark defines, $\mathbb{E}[R^2] = 0.50$. Any reported fit near
this value is uninformative. Section 4.2 reports observed medians of 0.66 in
Vietnam and 0.71 in Türkiye.

345 2.2.7. Inflation restatement as an exposure-by-post confound

We now formalise the accounting problem described in Section 3.1. Let A_{it} denote true non-monetary assets and D_{it} monetary debt. Under a general price-level restatement beginning at t_0 , non-monetary items are indexed by a factor depending on their *vintage*, while monetary items are not:

$$A_{it}^* = \Phi_{it} A_{it}, \quad D_{it}^* = D_{it}, \quad \log \Phi_{it} = (1 + \delta_i) c_t \mathbf{1}\{t \geq t_0\}, \quad (13)$$

350 where c_t is the common cumulative price-index component and δ_i is a firm-specific loading determined by the vintage profile of the firm's asset base, normalised so that $\mathbb{E}[\delta_i] = 0$.

Proposition 7 (Non-absorbability). *Let reported log leverage be $\ell_{it}^* = \log D_{it}^* - \log A_{it}^*$ and consider the two-way within regression of ℓ_{it}^* on $\theta_i P_t$ with $P_t =$*
 355 *$\mathbf{1}\{t \geq t_0\}$. Then*

$$\text{plim } \hat{\beta} = \beta - \bar{c} \frac{\text{Cov}(\theta_i, \delta_i)}{\text{Var}(\theta_i)}, \quad \bar{c} \equiv \mathbb{E}[c_t \mid t \geq t_0], \quad (14)$$

so the estimator is inconsistent whenever $\text{Cov}(\theta_i, \delta_i) \neq 0$, and the bias is not removed by firm or year effects.

Proof. Substituting (13), $\ell_{it}^* = \ell_{it} - c_t \mathbf{1}\{t \geq t_0\} - \delta_i c_t \mathbf{1}\{t \geq t_0\}$. The second term varies only with t and is absorbed by λ_t . The third term varies across
 360 firms and only after t_0 ; it is therefore collinear with the regressor $\theta_i P_t$ to the extent that δ_i covaries with θ_i , and projecting it onto $\theta_i P_t$ yields the stated bias. Firm effects α_i cannot absorb it because it is zero before t_0 and non-zero after. $\square$

Proposition 7 is the paper's central identification result and the rea-
 365 son we regard the Turkish post-2022 window as hazardous. The condition

$\text{Cov}(\theta_i, \delta_i) \neq 0$ is not a knife-edge case: δ_i depends on asset vintage, which correlates with capital intensity, sector and firm age, each of which correlates with financing structure and hence with any balance-sheet exposure measure. The usual defence—country-by-year fixed effects—absorbs c_t exactly and $\delta_i c_t$ not at all.

2.2.8. Flow ratios are invariant

The corresponding positive result identifies what survives.

Proposition 8 (Flow invariance). *Suppose income-statement items accruing within period t are restated by a common factor ψ_t that does not depend on i . Then for any two flows X_{it}, Z_{it} the reported ratio is exactly invariant, $X_{it}^*/Z_{it}^* = X_{it}/Z_{it}$; and for the implied borrowing cost $r_{it} = |\text{Int}_{it}|/\bar{D}_{it}$, which divides a restated flow by an unrestated monetary stock,*

$$\log r_{it}^* = \log \psi_t + \log r_{it}, \quad (15)$$

so that $\log r_{it}^*$ is contaminated only by an additive time effect, fully absorbed by λ_t .

Proof. Immediate from $X^* = \psi_t X$, $Z^* = \psi_t Z$ and $D^* = D$. $\square$

Remark 1. Proposition 8 is why our outcome set is restricted to the EBIT margin, interest coverage, the log implied rate and log debt growth, and why the Altman Z'' score, leverage, equity ratios and return on assets are discarded: each of the latter contains a non-monetary stock and is exposed to Proposition 7. It also refines the specification: the implied rate is invariant in logs, not in levels, and we use it accordingly.

2.2.9. Reading pass-through structurally

Finally, the framework gives the aggregate pass-through estimate an interpretation. Let the firm’s realised average cost be a maturity-weighted
390 average of past marginal rates,

$$r_{it} = \sum_{s \geq 0} \omega_{is} \iota_{t-s}, \quad \sum_{s \geq 0} \omega_{is} = 1, \quad (16)$$

where ι_t is the marginal contract rate and ω_{is} the share of debt priced s periods ago. Then $\partial r_{it} / \partial \iota_t = \omega_{i0} \equiv m_i$, the share repricing within the period, and aggregating, $\Delta \bar{r} / \Delta \bar{\iota} = \bar{m}$.

Corollary 9. *The aggregate pass-through coefficient identifies the mean ef-*
395 *fective repricing share $\bar{m}$ of the corporate debt stock.*

Section 4.1 estimates $\bar{m} \approx 0.35$ for Türkiye against a median short-term debt share of 0.63, implying that even nominally short debt repriced only partially—evidence, though not proof, of quantity rationing or subsidised credit substituting for full price adjustment.

400 3. Institutional setting and data

3.1. Institutional setting

3.1.1. Two monetary regimes

The Turkish tightening is the sharper of the two by an order of magnitude. After a period of unorthodox easing the one-week repo rate stood at 9.0%
405 at end-2022. Following the June 2023 reversal it reached 42.5% by end-2023, peaked at 50.0% in March 2024 and held there through November, before a December cut to 47.5%; it stood at 38.0% at end-2025. Consumer price

inflation exceeded 60% at its height and the lira depreciated from roughly 18.7 per US dollar at end-2022 to 43.0 at end-2025.

410 Vietnam’s experience is far milder. The State Bank raised policy rates in late 2022 amid stress in the domestic corporate bond market and reversed through 2023. The average bank lending rate rose from 8.0% in 2022 to 9.3% in 2023—against 17.0% at the peak of the 2011 inflation episode, a useful within-country benchmark for what a severe Vietnamese tightening looks
415 like.

The comparison is therefore not treatment versus control but large dose versus small dose, and the appropriate prediction is proportional rather than binary.

3.1.2. The Turkish accounting transition

420 Türkiye met the IFRS criteria for a hyperinflationary economy and was classified as such from April 2022, with local inflation-adjustment requirements following for statements through end-2023. Under the relevant standard, entities reporting in the currency of a hyperinflationary economy restate their statements in the measuring unit current at the balance sheet
425 date, and comparatives are restated on the same basis.

The mechanics are those assumed in (13). Non-monetary items—property, plant and equipment, inventories, equity—are restated by a general price index applied from each item’s acquisition date, so the effective factor depends on vintage. Monetary items—debt, cash, receivables—are already in period-
430 end purchasing power and are not restated. Income-statement items are restated to period-end purchasing power by a factor common across firms within a period, which is the condition of Proposition 8.

3.2. Data

3.2.1. Sources and construction

435 Two countries anchor the study and supply its decade-long identification tests: Vietnam and Türkiye, described below. Three further countries—Poland, Israel and South Korea—extend the 2021–2025 window across a range of monetary tightening between Türkiye and Vietnam. These three are built from Yahoo Finance directly: ticker universes are enumerated per
440 exchange via the TradingView screener, restricted to non-financial sectors, and statements retrieved as in the validation exercise of Section 4. Yahoo retains only four to five annual periods, so these three support the aggregate dose-response test of Section 5.3 but not the decade-long event-study test. Section 5.2 also requires for Türkiye and Vietnam; and by the feasibility
445 condition of Section 2.2, a four-year window is in any case well short of what firm-level repricing-sensitivity estimation needs, so no attempt is made to extend the beta estimation of Section 4 to them.

The Vietnamese panel derives from an item-level dataset of statements filed by companies listed on the Ho Chi Minh City and Hanoi exchanges, distributed through a public research repository in long format with standard-
450 ised item codes. Pivoting to firm-year observations yields 9,893 firm-years for 693 firms over 2011–2025, with non-missing coverage of 94.5% for total assets, 94.7% for total debt, 91.2% for interest expense, 93.2% for EBIT and 96.8% for equity.

455 The Turkish panel derives from a brokerage service redistributing filings made to the Public Disclosure Platform. One request returns the balance sheet, income statement, cash-flow statement and supplementary items with

bilingual labels for four annual periods. The resulting panel covers 585 firms over 2010–2025 and carries two items with no Vietnamese counterpart: export sales and net foreign-currency position.

Both panels are restricted to non-financial firms, since banks, insurers and brokers file on incompatible templates. We require strictly positive total debt and assets, the transmission channel being undefined otherwise. Table 1 reports firm counts by year: Turkish coverage rises as the exchange admits new listings over the sample, while Vietnamese coverage is near-complete from 2015. Because identification uses within-firm variation with firm fixed effects, this entry does not bias the estimates, though earlier years rest on a smaller Turkish cross-section.

Entry is not the whole story, and we state the remaining threat plainly rather than let the firm-fixed-effects argument above stand in for it. Both ticker universes are enumerated from a current listing snapshot: the Turkish panel is built by fetching statements for every presently BIST-listed company, and the three-country extension similarly enumerates each exchange’s current constituents. A firm that delisted, was acquired, or failed at any point in 2010–2025 is therefore absent from the panel not only after its exit but in every year it was ever observed, since it was never fetched in the first place. This is a materially different problem from the balanced-panel question fixed effects answer: an unbalanced panel with random entry and exit is unbiased under within-firm estimation, but non-random attrition—firms disappearing *because* of the shock we study—is not, and firm fixed effects do nothing to correct for a firm never entering the sample to begin with. For a paper whose outcomes are interest coverage, EBIT margin and debt growth under

a severe monetary tightening, the firms most likely to have failed *because* of that tightening are exactly the ones a current-snapshot ticker universe is least likely to include. We do not have a correction for this and flag it as an open limitation: the null we report describes the population of firms that survived to be listed as of data collection, and if distress-driven delisting is correlated with exposure, the true cross-sectional gradient among firms that failed could differ from what we estimate among firms that did not.

Table 1: Firms per year

Year	Türkiye	Vietnam	Year	Türkiye	Vietnam
2015	349	648	2021	551	691
2016	358	663	2022	568	692
2017	370	670	2023	585	693
2018	428	682	2024	584	692
2019	467	686	2025	582	689
2020	508	690			

3.2.2. Descriptive statistics

Table 2 summarises the two anchor panels over 2015–2025.

Leverage is comparable across markets at 20–25% of assets, and both corporate sectors fund themselves predominantly at short maturity; the Vietnamese median short-term share of 0.85 speaks to the rollover-risk framing of He and Xiong (2012). The contrast in distress is stark: median Turkish interest coverage is 1.07 against Vietnam’s 3.29, placing the median Turkish firm close to the covenant-relevant threshold Greenwald (2019) identifies.

Table 2: Descriptive statistics, 2015–2025

Variable	Vietnam				Türkiye			
	<i>n</i>	Mean	Median	SD	<i>n</i>	Mean	Median	SD
Debt / assets	5,708	0.250	0.225	0.170	4,780	0.228	0.195	0.190
Short-term debt share	5,708	0.709	0.852	0.323	4,783	0.627	0.647	0.284
Implied borrowing cost	5,693	0.063	0.063	0.032	3,870	0.312	0.252	0.219
Interest coverage	5,340	9.225	3.290	15.698	4,673	2.680	1.068	6.502
Return on assets	5,698	0.065	0.053	0.065	4,783	0.080	0.070	0.105

3.2.3. Cross-validation against an independent source

Because the subject is measurement, we test rather than assume our
500 panels. Table 3 reports the reconciliation.

Table 3: Reconciliation with an independent source

Variable	Vietnam		Türkiye	
	Corr.	Median diff.	Corr.	Median diff.
Total assets	1.0000	0.0000	0.9635	0.0000
Revenue	0.9999	0.0000	0.9431	0.0000
Total debt	0.9906	0.0000	0.8934	−0.0780
Equity	0.9956	−0.0447	0.8412	−0.0003
EBIT	0.7657	+0.2339	0.8499	+0.0798
Interest expense (abs.)	0.9913	0.0000	0.4950	−0.5955

Total assets and revenue reconcile at a median relative difference of zero in both countries, though the correlation is tighter in Vietnam (1.0000, 0.9999)

than Türkiye (0.9635, 0.9431). Equity differs by about four percent in Vietnam and negligibly in Türkiye, in each case because the aggregator reports
 505 parent-only equity where the national source consolidates minority interest; EBIT differs by 23% in Vietnam and 8% in Türkiye because the aggregator derives it from pretax income plus interest rather than reported operating profit. All of the above are definitional. The interest-expense discrepancy in Türkiye is not, and Section 4.1 is devoted to it.

510 4. Measuring the price of debt and firm exposure

4.1. The price of corporate debt

4.1.1. Construction and validation

For firm i in year t the implied borrowing cost is

$$r_{it} = \frac{|\text{Interest expense}_{it}|}{\frac{1}{2}(D_{it} + D_{i,t-1})}, \quad (17)$$

with D the sum of short- and long-term borrowings. Averaging the denominator prevents the ratio being driven mechanically by borrowing undertaken
 515 during the year. By Proposition 8, $\log r_{it}$ is contaminated only by an additive time effect under restatement, and we use logs throughout.

The measure is not calibrated to any policy series, so recovering one is a genuine test. Table 4 reports it.

520 Figure 1 plots the comparison. The Turkish series peaks in 2024, the year policy peaks. The Vietnamese series peaks in 2011 at the height of that country’s inflation crisis, falls monotonically to 5.8% by 2015, rises to 7.2% in the 2023 tightening and subsides. Median interest coverage moves in mirror image, reaching its Vietnamese sample minimum of 1.96 in exactly 2023.

Table 4: Median implied borrowing cost and the policy path

Vietnam			Türkiye		
Year	Implied	Lending rate	Year	Implied	CBRT policy
2011	11.1%	17.0%	2022	17.8%	9.0%
2013	7.5%	10.4%	2023	25.4%	42.5%
2015	5.8%	7.1%	2024	31.2%	47.5%
2020	6.3%	7.6%	2025	25.8%	38.0%
2023	7.2%	9.3%			
2025	5.8%	—			

Note: the CBRT column reports the December (year-end) reading each year, for consistency across the multi-year path. The true within-year peak was 50.0%, sustained from March through November 2024, before a December cut to the 47.5% shown; Section 4.1 uses the true peak, not the year-end reading, wherever pass-through is quantified.

Figure 1: Median implied borrowing cost against the policy path. The measure is constructed from firm financial statements alone and is not calibrated to any policy series.

525 4.1.2. *Pass-through*

Policy moved 41.0 points between end-2022 (9.0%) and the true 2024 peak (50.0%, sustained March through November, not the 47.5% year-end reading after the subsequent December cut); realised borrowing costs moved 13.4 points, from 17.8% to 31.2%. By Corollary 9 this identifies a mean effective
530 repricing share of $\bar{m} \approx 0.33$. Set against a median short-term debt share of 0.63, it implies that even nominally short debt repriced only partially. Over the same window median interest coverage halved, from 3.36 to 1.66. Vietnam’s mild cycle produces a proportionally mild response: costs move 0.76 points from 2022 to the 2023 tightening year, and coverage dips from
535 2.91 to 1.96 before recovering to 3.19 as policy reverses.

4.1.3. *A data hazard: bundled financial expense*

The Turkish field labelled *Financial Expenses* is the only interest-like item available before 2021 and is the natural candidate for the long history. It should not be used as one: against the independent aggregator it runs
540 roughly two and a half times larger, with a median relative difference of -59.6% and a correlation of only 0.495 on absolute values, against Vietnam’s 0.991 and 0.00%.

The field bundles foreign-exchange revaluation, and in a currency crisis those losses dwarf interest. The consequence is not attenuation but a change
545 in what is measured: built on the bundled field the Turkish implied cost peaks in **2018 and 2021**, the lira depreciation episodes; built on a clean interest figure it peaks in **2024**, with policy. A researcher using it to study monetary transmission would recover currency shocks and report them as interest-rate effects, with strong significance.

550 *4.2. Measuring exposure*

4.2.1. The required object is not disclosed

Contractual repricing basis does not appear in published statements under either regime. Firms disclose borrowings by maturity and sometimes currency, but not by repricing terms. We therefore assess the two constructible
555 substitutes.

4.2.2. Revealed repricing sensitivity

We estimate (6) firm by firm over a window ending before treatment. The FX term is included jointly rather than as a nuisance control, because Section 4.1 established that much of the movement in Turkish realised cost
560 is currency revaluation.

On conventional diagnostics the estimates behave: 71% of Vietnamese firms and 67% of Turkish firms return a positive $\hat{\theta}$, the mean Vietnamese estimate implies that a one-point rise in the lending rate raises a firm's cost of funds by roughly 0.79 points, and median in-sample R^2 is 0.29 in Vietnam
565 and 0.34 in Türkiye on the full 2012–2022 estimation window—a distinct quantity from the split-half-window fit of 0.66 and 0.71 reported above and in Table 5 below, since the two are computed on windows of different length. Propositions 2–6 supply the tests these diagnostics cannot pass, reported in Table 5.

570 By Proposition 2 these correlations *are* the reliability ratio λ . Both are within 0.06 of zero, so by Corollary 3 the treatment estimand is attenuated to essentially zero and carries almost no information about β . The measured balance-sheet characteristics in the lower rows behave as far more stable traits, so the failure is specific to regression-estimated quantities.

Table 5: Split-half reliability of candidate exposure measures

Each firm’s usable years are partitioned into two halves 200 times, independently at random; the table reports the correlation between the two halves’ estimates, averaged across the 200 partitions, by country. The computation is scripted in full in the accompanying replication code.

Measure	Türkiye	Vietnam
Repricing sensitivity $\hat{\theta}$	+0.045	+0.054
FX sensitivity $\hat{\gamma}$	+0.003	+0.059
Short-term debt share	+0.828	+0.903
Export share	+0.935	—

Table 6: Variance decomposition of estimated repricing sensitivities

	Vietnam	Türkiye
$\text{Var}(\hat{\theta})$	5.25×10^{-4}	1.30×10^{-4}
Sampling component σ_u^2	4.03×10^{-5}	4.35×10^{-5}
Reliability implied by sampling noise alone	0.923	0.664
Measured split-half correlation	+0.054	+0.045
Permanent component σ_θ^2	2.85×10^{-5}	5.88×10^{-6}
Transitory component σ_ν^2	4.96×10^{-4}	1.24×10^{-4}
Transitory share of dispersion	94.6%	95.5%

575 Table 6 applies Proposition 5 and delivers the paper’s sharpest method-
ological finding. Sampling noise alone implies reliabilities of 0.923 and 0.664:
a conventional power calculation, or an inspection of standard errors, would
have judged the Vietnamese design comfortably feasible and the Turkish one
feasible or close to it. The split-half correlations nonetheless leave almost
580 none of that dispersion permanent, attributing 94.6% of Vietnamese and
95.5% of Turkish dispersion to a transitory component.

The distinction matters for what one should do about it. Imprecision
is remediable with more data; impermanence is not. A firm’s estimated
repricing sensitivity is real within the window in which it is measured and
585 does not persist beyond it, so it cannot serve as a pre-determined regressor for
a treatment occurring later. Quarterly estimation would raise T and shrink
 σ_u^2 , which Table 6 shows was never the binding constraint.

4.2.3. First-stage prediction

The decisive test asks whether $\hat{\theta}$ predicts what it purports to, reported
590 in Table 7.

Table 7: Does estimated exposure predict the actual change in borrowing cost?

	Türkiye (2022–24)	Vietnam (2022–23)
Coefficient on $\hat{\theta}$ (standardised)	−0.036	+0.001
p -value	0.27	0.54
R^2	0.035	0.002
Change, lowest tercile	+0.19	+0.006
Change, highest tercile	+0.04	+0.010

In Türkiye the most-exposed tercile records the *smallest* increase in realised cost. Median in-sample fit on the split-half windows is 0.66 in Vietnam and 0.71 in Türkiye against the null benchmark $k/(T-1) = 0.50$ of Proposition 6—the same order of magnitude as chance, and neither approaches the fit a genuine two-parameter relationship would typically produce.

4.2.4. *Balance-sheet proxies*

The measured characteristics are reliable but do not identify repricing. Regressing the actual change in borrowing cost on standardised pre-period characteristics yields R^2 below 0.02 for the short-term debt share, leverage, the current ratio, size and interest coverage, in both countries.

The short-maturity share illustrates the confound. It is simultaneously a measure of repricing exposure and of credit quality, since firms able to roll short-term paper cheaply are disproportionately the strongest borrowers. In Türkiye the two align and coverage falls monotonically across terciles; in Vietnam the credit-quality effect dominates and the ordering inverts, the most short-funded tercile being the healthiest in most years (5.02 against 3.45 in 2021). A proxy whose sign flips across two structurally similar markets is not measuring a single construct.

5. Identification, results and robustness

5.1. *Identification*

5.1.1. *The restatement confound, empirically*

Table 8 reports the Turkish median balance-sheet aggregates.

Median leverage more than halves between 2019 and 2024 while equity-to-assets rises by over twenty points, in a period of severe tightening and

Table 8: Turkish median balance-sheet aggregates

Year	Equity / assets	Debt / assets
2017	0.472	0.217
2019	0.419	0.226
2021	0.462	0.189
2022	0.558	0.138
2023	0.614	0.111
2024	0.646	0.100
2025	0.619	0.117

615 depreciation during which no such deleveraging occurred. The break begins in 2022, consistent with the April 2022 classification and the restatement of comparatives.

Proposition 7 predicts that a design using stock-based outcomes will be inconsistent whenever $\text{Cov}(\theta_i, \delta_i) \neq 0$. Estimating it with FX exposure as
620 treatment returns exactly that pathology: coefficients that are highly significant and wrongly signed, with firms holding more foreign-currency debt appearing to *improve* after 2023 (implied rate -0.108 , $p < 0.0001$; Altman Z'' (Altman, 2005) $+0.813$, $p = 0.004$; leverage -0.049 , $p < 0.0001$); an event-study path growing monotonically as restatement compounds ($+0.32$,
625 $+0.83$, $+1.18$ across 2023–2025); and large significant pre-treatment coefficients. The result has every outward mark of a strong causal finding and is an accounting artefact.

5.1.2. The surviving specification

Propositions 7 and 8 imply three restrictions. Outcomes must be flows:
630 we retain the log implied rate, interest coverage, EBIT margin and log
debt growth, and discard leverage, equity ratios, return on assets and the
emerging-market Altman Z'' score of Altman (2005), each of which combines
a monetary numerator with a non-monetary stock. Exposure must predate
the restatement, and we measure it at 2021. And the pre-period must per-
635 mit a test of parallel trends; because EBIT margin and debt growth require
no interest figure, the bundling problem of Section 4.1 is irrelevant to them
and the national source’s history back to 2015 can be used. The estimating
equations are (1) and its dynamic analogue

$$Y_{it} = \sum_{k \neq 2022} \beta_k (E_i \cdot \mathbf{1}\{t = k\}) + \alpha_i + \lambda_t + \varepsilon_{it}, \quad (18)$$

with 2022 omitted and standard errors clustered by firm (Petersen, 2009).
640 Because treatment timing is common within country we avoid the negative-
weighting and heterogeneity problems identified by Goodman-Bacon (2021),
de Chaisemartin and D’Haultfœuille (2020), Callaway and Sant’Anna (2021)
and Sun and Abraham (2021), so the two-way estimator remains inter-
pretable here; following Roth (2022) we report full event paths rather than
645 conditioning on a pre-trend test statistic.

5.2. Results

Four coefficients reach conventional significance. The event studies show
none is a treatment effect; Table 10 reports the sharpest case.

Figure 2 makes the point visually. Firms with more short-term debt
650 grow debt more slowly in every year from 2015 onward, and the coefficient at

Table 9: Main estimates: exposure $\times$ post, flow outcomes

Country	Exposure / Outcome	Firms	Coef.	SE	<i>p</i>
TR	Short-term share / implied rate	466	0.018	0.016	0.27
TR	Short-term share / coverage	468	−0.421	0.718	0.56

TR	FX exposure / implied rate	491	−0.025	0.021	0.23
TR	FX exposure / coverage	498	0.176	0.733	0.81
TR	FX exposure / EBIT margin	547	0.023	0.011	0.04
TR	FX exposure / debt growth	536	−0.055	0.028	0.05
VN	Short-term share / implied rate	522	−0.002	0.001	0.11
VN	Short-term share / coverage	521	−0.355	0.497	0.48
VN	Short-term share / EBIT margin	522	−0.016	0.004	0.00
VN	Short-term share / debt growth	522	0.059	0.019	0.00

Table 10: Event study: Turkish short-maturity share on debt growth (base 2022)

Year	Coef.	SE	Year	Coef.	SE
2015	−0.138**	0.068	2021	−0.232***	0.066
2016	−0.187***	0.065	2022	base	—
2017	−0.162***	0.062	2023	−0.220***	0.069
2018	−0.189***	0.072	2024	−0.069	0.076
2019	−0.252***	0.070	2025	−0.191***	0.064
2020	−0.211***	0.057			

Figure 2: Event studies of exposure interacted with year, with firm and year effects and 95% confidence intervals clustered by firm. The dashed line marks the treatment date. Coefficients are non-zero well before treatment and do not shift at it.

treatment is statistically indistinguishable from those seven years earlier. The Vietnamese EBIT-margin result has the same character, drifting from +0.020 ($p < 0.01$) in 2015 to -0.011 ($p < 0.10$) in 2025 and passing smoothly through the treatment year. These are persistent differences between firm types, not
655 responses to monetary policy. What a conventional two-year window would report is the difference between the 2022 base and the 2023–25 average—a difference that exists, is significant, and means nothing causal.

5.3. Cross-country evidence: dose-response and pooled exposure

The two-country design identifies the exposure gradient cleanly but leaves
660 open whether its absence is a Türkiye-and-Vietnam idiosyncrasy or a general property of listed emerging-market firms. We extend the price validation of Section 4 and the exposure test of this section to the five-country, 2021–2025 sample described in Section 3.2, spanning tightening doses from Türkiye’s 36.0 percentage points to Vietnam’s 1.5.

Table 11: Dose-response across five countries, 2022 to 2023–24

Country	Dose (pp)	Firms	Δ Implied rate (pp)	ICR pre	ICR post
Türkiye	36.00	559	10.59	3.36	2.45
Poland	5.00	521	1.59	4.72	2.91
Israel	4.65	274	1.90	4.81	3.29
South Korea	2.50	290	1.56	6.19	4.16
Vietnam	1.51	570	0.13	2.91	2.23

665 The change in implied borrowing cost correlates with policy dose at $r = 0.995$ across the five countries, and median interest coverage falls in

every single one, from Türkiye’s 36.0-point tightening down to Vietnam’s 1.5. Figure 3 plots the relationship.

Figure 3: Change in median implied borrowing cost against policy tightening dose, five countries, 2022 to 2023–24. The measure is constructed from firm statements alone.

A correlation of 0.995 on five points warrants an immediate caveat rather
 670 than a boast, and we give it here rather than let the reader discover it in-
 dependently. With $n = 5$, a very high correlation is close to mechanical:
 four of the five points already sit on an economically reasonable line, and a
 fifth far enough from the others (Türkiye) will produce a high r regardless of
 the details of the middle three. We therefore read Table 11 qualitatively—
 675 interest coverage deteriorates in every country, in rough proportion to tight-
 ening severity, and the pattern is consistent with the four additional markets
 assembled but not carried into this table (see the footnote to Section 1)—
 rather than treating 0.995 as a precisely estimated population parameter.
 The qualitative claim is the one this design can support; the correlation

680 coefficient illustrates it and should not be read as more than that.

We then pool all five countries and estimate the triple interaction

$$Y_{ict} = \beta_1(E_i P_t) + \beta_2(E_i P_t \cdot \text{Dose}_c) + \alpha_i + \lambda_{ct} + \varepsilon_{ict}, \quad (19)$$

with E_i the pre-period short-term debt share (the only exposure proxy constructible on a four-year panel), Dose_c the country's standardised tightening severity, and λ_{ct} country-by-year effects. If the exposure gradient were real
685 and simply underpowered in Section 5.2's two-country test, β_2 should be positive and significant on distress outcomes as dose rises. Table 12 reports the estimates.

Table 12: Pooled exposure $\times$ dose interaction, five countries

Outcome	Firms	β_1 (p)	β_2 (p)
Interest coverage	598	-0.977 (0.071)	0.050 (0.840)
EBIT margin	598	-0.008 (0.136)	-0.009 (0.414)
Implied rate	604	0.008 (0.073)	0.032 (0.047)

The dose interaction is null on both distress outcomes: interest coverage ($p = 0.840$) and EBIT margin ($p = 0.414$) show no evidence that the exposure gradient steepens with tightening severity. It is significant only for the
690 implied rate itself ($p = 0.047$)—the mechanical restatement, at firm level, of the aggregate result already established in Table 11, not a new finding about cross-sectional exposure. Scaling the test across a range of monetary shocks that spans more than an order of magnitude produces the same conclusion
695 as the two-country design: the price of debt responds to dose, the firm-level exposure gradient does not.

We emphasise the limits of this extension. The short-term debt share is the proxy shown in Section 4.2 to conflate repricing exposure with credit quality, and the four-year panel available for Poland, Israel and South Korea is, by the feasibility condition of Proposition 4, too short to support the reliability-tested repricing beta of Section 4.2. This subsection therefore corroborates the two-country null under a cruder exposure measure and a wider dose range; it does not repeat the decade-long identification test, which remains specific to Türkiye and Vietnam. Nor have these three countries been cross-validated against an independent second source in the manner of Section 4’s reconciliation exercise, which was performed only for Vietnam and Türkiye; their statement quality is assumed rather than independently verified, a limitation the two-country panels do not share.

5.4. Robustness

Placebo treatment. Assigning a false treatment at 2018 and restricting to 2015–2021 returns nothing for Vietnam: -0.791 ($p = 0.19$) on interest coverage and $+0.004$ ($p = 0.51$) on EBIT margin. The design is not mechanically generating significance, which supports reading Section 5.2’s significant coefficients as genuine pre-existing trends.

Sample-size stability. The Turkish estimates were computed at three sample sizes as collection proceeded. At 83 firms the specification returned $+0.886$ on the Altman Z'' score ($p = 0.045$) with significant pre-trends; at 158 firms both vanished; at 585 firms the estimates are those of Table 9. Roughly a third of the eventual sample produced a significant wrong-signed result with apparent pre-trend violation.

Alternative specifications.. Results are unchanged under winsorisation at 1%/99% rather than 2%/98%; exposure measured at 2020 or as the 2020–21 mean; exclusion of the smallest asset tercile; and exclusion of 2022 to guard against restated comparatives.

725 *What would overturn the null..* Table 6 is explicit that quarterly estimation would shrink σ_u^2 , which was not the binding constraint, and would leave σ_v^2 untouched. Portfolio sorting would average away the transitory component at the cost of the heterogeneity that motivates the exercise. Machine-readable disclosure of repricing basis would remove the problem entirely.

730 **6. Discussion and conclusion**

6.1. Implications for practice

Validate the price measure against the policy path. A measure that cannot reproduce a known aggregate should not be used to estimate an unknown cross-section; this test is what exposed the bundled-expense problem.

735 *Report split-half reliability whenever exposure is estimated.* By Proposition 2 it is the attenuation factor itself, not merely a diagnostic correlated with it, and by Proposition 5 it separates imprecision from impermanence. Standard errors and power calculations cannot: in our data they indicated reliabilities of 0.664–0.923 where the split-half estimate of the true permanent
740 share was under 6%.

In inflation-accounting regimes, prefer flows. By Proposition 7 the contamination enters as an interaction and fixed effects do not address it; by Proposition 8 ratios of flows escape it.

Extend the pre-period until parallel trends can genuinely be tested. Restricting to outcomes with long history revealed that our significant coefficients were decade-long trends; a two-year window would have produced a publishable false positive.

6.2. Conclusion

Published financial statements support a genuine, validated measure of the price of corporate debt, and it recovers monetary policy paths in a severe Turkish tightening and a mild Vietnamese one. Using it we document pass-through of roughly one-third, a halving of median Turkish interest coverage, and a data field that conflates currency shocks with interest costs.

Statements do not support a measure of which firms are contractually exposed to repricing. Our framework explains why in a form that is testable rather than rhetorical: the estimand is attenuated by the reliability of the exposure proxy, that reliability is identified by a split-half correlation which is indistinguishable from zero in both countries, and the dispersion in estimated sensitivities is overwhelmingly transitory rather than permanent—so the failure is impermanence, which more data cannot cure.

The implication is not that the channel fails to operate; our aggregate evidence is consistent with its operating forcefully in Türkiye. It is that the cross-sectional question—*which* firms bear the adjustment—requires contractual data. Researchers without registry access should direct effort toward the aggregate and price-side questions statements can answer, and toward making repricing terms disclosable, rather than toward proxies that cannot carry the weight placed on them.
